An analytical model for embedment stiffness of a dowel in timber under cyclic load

Thomas Reynolds · Richard Harris · Wen-Shao Chang

Received: 31 January 2013/Published online: 24 June 2013 © Springer-Verlag Berlin Heidelberg 2013

Abstract The fundamental part of a dowel-type connection is the embedment of a steel dowel into the timber that surrounds it, and the stiffness of the timber in embedment is represented by the foundation modulus. A standard experimental method for identifying the foundation modulus under static load is modified to assess the secant stiffness exhibited under one-sided cyclic load. It is shown that the steady-state secant stiffness is significantly higher than the static stiffness under initial loading, and that, if the amplitude of the cyclic component of the load is sufficiently small, a simple analytical elastic model predicts the foundation modulus well. The analytical model is based on a complex stress function for the timber in embedment and the frictional interaction between the dowel and the timber. The foundation modulus calculated in this way can be used to predict the stiffness of complete connections for analysis of vibration in frames modelled with semi-rigid joints. Although the application of the model is limited to vibration about a non-zero mean load, with no load-sign reversal, this form of vibration encompasses various important types of in-service vibration of structures, such as that induced by turbulent wind or footfall.

Ein analytisches Modell zur Bestimmung der Lochleibungssteifigkeit einer stiftförmigen Verbindung bei zyklischer Belastung

Zusammenfassung Bei stiftförmigen Verbindungsmitteln ist die Bettung eines Stahldübels im umliegenden Holz

T. Reynolds (⋈) · R. Harris · W.-S. Chang BRE Centre for Innovative Construction Materials, Department of Architecture and Civil Engineering, University of Bath, Claverton Down, Bath BA2 7AY, UK e-mail: tpsr20@bath.ac.uk von grundlegender Bedeutung. Die Steifigkeit des Holzes im Bereich der Lochleibung wird anhand des Bettungsmoduls ausgedrückt. Zur Beurteilung der bei zyklischer Schwellbelastung auftretenden Sekantensteifigkeit wurde ein Standardprüfverfahren zur Bestimmung des Bettungsmoduls bei statischer Belastung modifiziert. Es wurde gezeigt, dass die stationäre Sekantensteifigkeit signifikant höher ist als die statische Steifigkeit bei Anfangsbelastung und dass bei einer ausreichend kleinen Amplitude der zyklischen Belastungskomponente ein einfaches analytisches elastisches Modell zur Bestimmung des Bettungsmoduls gut geeignet ist. Das analytische Modell basiert auf einer komplexen Spannungsfunktion des Holzes im Bereich der Lochleibung sowie der Reibung zwischen Dübel und Holz. Der so berechnete Bettungsmodul kann bei den Schwingungsberechnungen in Tragwerken mit modellierten nachgiebigen Verbindungen zur Bestimmung der Steifigkeit dieser Verbindungen verwendet werden. Obwohl das Modell nur für eine Schwellbelastung gilt, deckt diese doch verschiedene wichtige Schwingungsbeanspruchungen in Bauwerken ab, wie zum Beispiel Wind- oder Trittbeanspruchung.

1 Introduction

Wind, footfall and machinery can cause vibration in structures. Vibration above a certain level may be perceived by occupants or users of the structure, and this can lead to complaint. While such vibration may not necessarily cause structural damage, complaint by users represents a serviceability failure, which may result in additional costs in modifying the structure to perform appropriately, and may also reduce public confidence in a particular form of construction. Such phenomena are magnified by the light

weight and flexibility of timber and engineered timber products, when compared to alternative structural materials.

In order to reduce the likelihood of excessive vibration, the structural engineer must have accurate design parameters. One important parameter is the stiffness exhibited by the system. To predict the behaviour of a structure, the stiffness properties of each component of the structure must be known, and the stiffness of connections can be an important factor in the design of timber structures. The foundation modulus is the stiffness, per unit length of connector, of the resistance of the timber to the embedment of a rigid dowel. It can be used as a fundamental parameter in assessing the stiffness of dowel-type connections. Dowel-type connections are widely used, and include nails, screws, bolts and plain dowels.

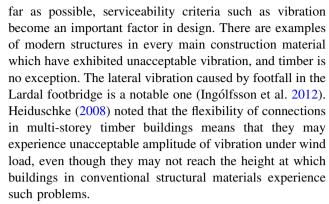

In this paper, the foundation modulus applicable to vibrations has been investigated, by means of experimental work on the interaction between timber and connector under dynamic load. The foundation modulus for a single dowel has also been theoretically estimated based on the orthotropic elastic properties of the timber and the coefficient of friction between the steel and the timber. Material properties for the theoretical model are obtained through tests on specimens extracted from the dynamic test pieces, and the predictions are tested against the experimental results.

This secant foundation modulus is based on the relative deformation of the timber around the dowel for each cycle of applied force. It differs from the static foundation modulus, which is based on the total deformation of the timber under a gradually applied force. The secant foundation modulus is higher than the static value, since the latter includes the effect of a low initial stiffness, resulting from any lack of fit between the dowel and the hole in the timber, and the imperfection of the contact surface between dowel and timber.

This analytical and experimental work focusses on vibration without load sign reversal, so, throughout the cycle, a compressive force is maintained on the specimen. This is an important form of in-service vibration since it corresponds, for example, to footfall-induced vibration, where the self-weight and imposed load on the structure provides a mean force about which the footfall force induces oscillation. A similar form of vibration occurs as a result of turbulent wind load on a structure, in which the mean wind force is greater than the oscillating component caused by turbulence.

2 Background

As structural engineers strive to create more efficient structures, reducing the self-weight of floors and bridges as

Dowel-type connections are widely used in timber structures, and their relative flexibility means that they play an important role in the behaviour of the structure as a whole, under both static and dynamic load. Researchers have investigated the contribution of dowel-type connections to the behaviour of trusses (Larsen and Jensen 2000), sheathed wall panels (Šilih et al. 2005) and frames with moment connections (Nishiyama and Ando 2003). Larsen and Jensen (2000) identify the conditions under which a semi-rigid joint analysis is possible, including the tight fit of connectors to avoid unpredictable initial slip.

Experimental campaigns have been carried out to identify the force–displacement response of dowel-type connections between timber elements under cyclic loads (Allotey and Foschi 2004; Foliente 1995; Foschi 2000; Heiduschke 2006a; Noguchi and Komatsu 2004), and the results have been used to develop models of the joints. These focus predominantly on the post-yield behaviour applicable to seismic and extreme wind events.

The joint model can then be used to form part of a numerical model of a complete structure. This type of analysis can be used to assess the behaviour of existing forms of construction under dynamic loading, as was done by He (2001) and Heiduschke (2006b), or to predict the performance of proposed devices and techniques, as by Loo et al. (2012) for slip-friction connectors, or by Awaludin et al. (2008) for pretensioned bolts.

Small-amplitude vibration of timber structures in service differs in two ways from seismic loading: one is that neither the timber nor the steel yields, though the behaviour of the timber cannot be expected to be completely linear. The other is that the vibrations are often one-sided. That is to say, the vibrations are often small-amplitude oscillations around a non-zero mean, with no reversal of the load. This is the case for footfall-induced vibration of floors and bridges, as well as along-wind vibration of structures due to turbulent wind load. Under one-sided vibration, the secant stiffness of the connections is independent of the initial slip, which has already occurred, and so the condition given by Larsen and Jensen (2000) for analysis with semirigid joints is met.

Tests on completed timber buildings to investigate their behaviour in response to small vibrations are rare. One example, for the widely used sheathed stud wall form of construction, is Ellis and Bougard's investigation of the BRE Timber Frame 2000 building (Ellis and Bougard 2001).

This paper seeks to provide a basis for predicting the response of timber structures with dowel-type connections to small vibrations, based on the fundamental material properties and geometry of the connection. The pre-yield behaviour of a dowel-type connector in timber is investigated by considering it as a pin-loaded orthotropic elastic plate. A complex stress function for an orthotropic plate in plane stress, with a hole loaded along its edge, was proposed by Lekhnitskii (1968). This general form of the function was adapted to the particular case in which the load on the edge of the hole is applied by a rigid circular section, referred to as a pin-loaded plate, by De Jong (1977). Different forms of the function have been developed to investigate various phenomena affecting the behaviour of the pin-loaded plate. Zhang and Ueng (1984) incorporated the effect of friction at the interface between pin and plate and Hyer and Klang (1985) allowed for deformation of the pin and clearance between the hole and the pin, as well as friction.

Despite the availability of nonlinear finite element modelling software capable of dealing with this geometry and loading, there continues to be research interest in the stress function approach, such as the development of a new form of solution by Aluko and Whitworth (2008). One reason for the enduring interest in this approach is the speed of calculation, and Derdas and Kostopoulos (2011) use the stress function to define the loading along the hole edge, and apply that loading to a finite element model, thus reducing the finite element model to a linear elastic one and avoiding the computational cost of carrying out a contact-element analysis.

The potential for application of this method to timber has been clear since Lekhnitskii (1968) used the material properties for plywood in the example calculations in his book. The further research described above was, however, generally motivated by the use of pin-jointed composites in aircraft and it was Echavarría et al. (2007) who noted its potential for application to dowel-type connections in timber structures, and developed a particular form of the stress function for that purpose.

All of the above researchers used the complex stress function approach as a tool for analysis of the stress distribution around the pin. Since the stress function defines the strain field in the plate, it can also be used to consider deformation of the connection, and it is on that aspect that this research focusses.

Sjödin et al. (2006) measured the strain field in the timber around a group of dowels, and showed that an elastic orthotropic plane-stress model for the timber could accurately represent the strain distribution. The same researchers then showed the influence of friction between the dowel and the timber on that strain distribution (Sjödin et al. 2008). The interaction between dowel and timber is nonlinear not just because of the friction between the two, however, but also because the timber surface is initially uneven, and this unevenness is compressed under load, improving the contact surface. This effect is discussed by Dorn et al. (2013), who suggested that the low initial stiffness may be due to the compression of the unevenness in the contact surface, and noted that under unloading and reloading the embedment behaviour is closer to linear elastic, as the surface of the timber remains compressed to its previous level. In his PhD thesis, Dorn (2012) modelled the load-displacement behaviour of the contact surface using the overclosure in a contact element analysis of a connection, and successfully represented the loading, unloading and reloading response.

This research presents and tests a model for embedment in the form of an analytical set of equations which takes into account the interface friction and the orthotropy elasticity of the timber. The effect of unevenness of the contact surface is not taken into account in this model, meaning that it is appropriate only to the secant stiffness under cyclic loading, in which the contact surface is assumed to have been compressed to provide a relatively stiff transfer of load to the timber. The model is therefore verified against cyclic loading tests.

3 Materials and methods

3.1 Analytical method

The load–deflection response of a circular dowel embedding into a piece of timber depends on the orthotropic elastic behaviour of the timber, and also on the frictional interaction between the dowel and the timber. The deformation of the cross-section of the steel dowel is assumed to be negligible, but the friction between the steel and timber determines the distribution of the forces around the face of the timber, so must be modelled.

This method has been developed on the assumption that, under small-amplitude vibration significantly below the embedment strength, the behaviour of the timber can be treated as linear, and therefore modelled using an orthotropic linear elastic model. The appropriateness of this assumption is discussed later in this paper, with reference to the experimental results.

In the model, the foundation modulus for the timber is estimated using a stress function of the form first proposed by Lekhnitskii (1968), and, in particular, as derived by Zhang and Ueng (1984). The definition of the stress function exactly follows the work of these researchers, and the formulae are collated and reproduced in this paper for convenience. The work of these researchers is then extended to assess the deformations in a specimen by superposition of two semi-infinite plate solutions.

The stress function represents the stresses in a semiinfinite orthotropic plate with a half-hole in the surface. The forces applied by the dowel along the surface of the half-hole are defined on the basis of the geometry and the coefficient of friction between the steel and the timber. The geometry and notation are shown in Fig. 1.

3.1.1 General form of stress function

Lekhnitskii (1968) showed that the general form of the stress functions for an infinite orthotropic plate with a hole is as given by (1) to (5). The solution of a particular problem relies on finding the coefficients a_n and b_n which correspond to the distribution of the load on the edge of the hole. $\zeta_{I,2}$ are transformed coordinates describing the point on the plate under consideration. Given the complex stress functions Φ_I and Φ_2 , the displacements u in the x direction and y in the y direction are given by (6) and (7). i is the imaginary unit.

 Φ_I and Φ_2 are stress functions defined by their relationship to the direct and shear stresses in the plate: the direct stress in the x direction, for example, is given by $\sigma_x = 2Re(\mu_1^2\Phi_1' + \mu_2^2\Phi_2')$ where Φ_1' is the derivative of Φ_1 with respect to z_I , and Φ_1' the derivative of Φ_2 with respect to z_2 . Re(I) denotes the real part of what is, in general, a complex number in the brackets, and μ_I and μ_2 are complex constants derived from the material properties of the plate, as in (8) and (9).

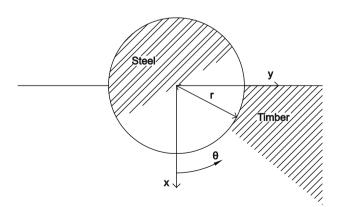

Fig. 1 Geometry for analysis Abb. 1 Geometrische Grundlagen

This work is not concerned with the stresses in the plate, but rather the relative displacements. The displacements in the plate are given by the integral of the strains, and are therefore proportional to the integral of the stresses. The displacements are therefore calculated using the undifferentiated stress functions Φ_1 and Φ_2 . A full derivation of the general form of the stress functions and their relationship to stresses, strains and displacements is given by Lekhnitskii (1968).

$$\Phi_1 = a_0 \ln \zeta_1 + \sum_{n=2}^{\infty} \frac{a_n}{\zeta_{1,n}}$$
 (1)

$$\Phi_2 = b_0 \ln \zeta_2 + \sum_{n=2}^{\infty} \frac{b_n}{\zeta_{2,n}}$$
 (2)

$$\zeta_1 = \frac{z_1 + \sqrt{z_1^2 - (1 + \mu_1^2)}}{r^2 (1 - i\mu_1^2)} \tag{3}$$

$$\zeta_2 = \frac{z_2 + \sqrt{z_2^2 - \left(1 + \mu_2^2\right)}}{r^2 \left(1 - i\mu_2^2\right)} \tag{4}$$

$$z_1 = x + \mu_1 y \quad z_2 = x + \mu_2 y \tag{5}$$

$$u = 2\text{Re}(p_1\Phi_1 + p_2\Phi_2) + U \tag{6}$$

$$v = 2\operatorname{Re}(q_1\Phi_1 + q_2\Phi_2) \tag{7}$$

u is the displacement relative to a particular fixed point, and includes one non-zero constant of integration, U. μ_1 , μ_2 , p_1 , p_2 , q_1 and q_2 are derived from the material properties of the plate material, the timber, as in (8)–(13), where E_1 is the elastic modulus of the plate material in the x direction, E_2 the elastic modulus in the y direction, G is the shear modulus, and v_1 the Poisson's ratio.

$$\mu_1^2 = \frac{2v_1 - \frac{E_1}{G} + \sqrt{\left(2v_1 - \frac{E_1}{G}\right)^2 - \frac{4E_1}{E_2}}}{2} \tag{8}$$

$$\mu_2^2 = \frac{2\nu_1 - \frac{E_1}{G} - \sqrt{\left(2\nu_1 - \frac{E_1}{G}\right)^2 - \frac{4E_1}{E_2}}}{2} \tag{9}$$

$$p_1 = \frac{\mu_1^2}{E_1} - \frac{v_1}{E_1} \tag{10}$$

$$p_2 = \frac{\mu_2^2}{E_1} - \frac{v_1}{E_1} \tag{11}$$

$$q_1 = \frac{1}{\mu_1 E_2} - \frac{\nu_1 \mu_1}{E_1} \tag{12}$$

$$q_2 = \frac{1}{\mu_2 E_2} - \frac{\nu_1 \mu_2}{E_1} \tag{13}$$

Lekhnitskii (1968) presents a method to allow the stress functions to be defined on the basis of the trigonometric series defining the displacements u' and v' on the hole edge.

The general form of those series is as in (14) and (15). $\sigma = e^{i\theta}$, α_m and β_m are coefficients determined by the boundary conditions and * denotes the complex conjugate.

$$u' = \alpha_0 + \sum_{m=1}^{\infty} (\alpha_m \sigma^m + \alpha_m^* \sigma^{-m})$$
 (14)

$$v' = \beta_0 + \sum_{m=1}^{\infty} (\beta_m \sigma^m + \beta_m^* \sigma^{-m})$$
 (15)

Once the coefficients are determined, they can be used to generate the stress functions using (16) to (19), where $D = p_1q_2 - p_2q_1$. Note that α_0 and β_0 do not affect the stress distribution in the plate. The overall movement of the hole, caused by a net force P on the hole, is allowed for by A and B.

$$\Phi_{1}(z_{1}) = A \ln \zeta_{1} + \frac{\left(\alpha_{1}^{*} q_{2} - \beta_{1}^{*} p_{2}\right)}{D \zeta_{1}} + \frac{1}{D} \sum_{m=2}^{\infty} \left(\alpha_{m}^{*} q_{2} - \beta_{m}^{*} p_{2}\right) \zeta_{1}^{-m} \tag{16}$$

$$\Phi_{2}(z_{2}) = B \ln \zeta_{2} + \frac{\left(\alpha_{1}^{*} q_{1} - \beta_{1}^{*} p_{1}\right)}{D \zeta_{2}} + \frac{1}{D} \sum_{m=2}^{\infty} \left(\alpha_{m}^{*} q_{1} - \beta_{m}^{*} p_{1}\right) \zeta_{2}^{-m} \tag{17}$$

$$A = \frac{P}{\pi i} \left(\frac{\mu_1 \mu_1^* + \mu_1 \mu_2^* - \frac{a_{12}}{a_{22}} \mu_1 \mu_2 \mu_1^* \mu_2^*}{(\mu_1 - \mu_1^*)(\mu_1 - \mu_2)(\mu_1 - \mu_2^*)} \right)$$
(18)

$$B = \frac{P}{\pi i} \left(\frac{\mu_2 \mu_2^* + \mu_2 \mu_1^* - \frac{a_{12}}{a_{22}} \mu_2 \mu_1 \mu_2^* \mu_1^*}{(\mu_2 - \mu_2^*)(\mu_2 - \mu_1)(\mu_2 - \mu_1^*)} \right)$$
(19)

3.1.2 Boundary conditions

Zhang and Ueng (1984) used the displacement boundary conditions described in (20) to (22), for the geometry shown in Fig. 1, to define the stress functions. In doing so, they assumed that the dowel remained rigidly circular, so that the radial displacement of the timber equals that of the face of the dowel, and that some slip occurs in the tangential direction, at all points except $\theta=0$.

$$u = \frac{u_0}{c}$$
 and $v = 0$ when $\theta = \pm \frac{\pi}{2}$ (20)

$$u = u_0$$
 and $v = 0$ when $\theta = 0$ (21)

$$(u_0 - u)\cos\theta = v\sin\theta \quad \text{when } \frac{-\pi}{2} \le \theta \le \frac{\pi}{2}$$
 (22)

 u_0 is, therefore, the displacement of the dowel in the semi-infinite plate, and c represents the extent to which the dowel slips along the surface of the timber. Zhang and Ueng (1984) proposed the trigonometric series in (23) to (31) to satisfy these boundary conditions. Using

this series, the standard form of stress function defined by (14) and (15), the stress functions for this particular case are defined as in (32) and (33). It can be seen that the friction coefficient μ affects the slip c, since it appears in the equations for the constants A_I and B_I , which also depend on the material properties of the timber.

$$u' = \frac{c-1}{2c}u_0\cos 2\theta + \frac{c+1}{2c}u_0\cos 4\theta \tag{23}$$

$$v' = \left(\frac{c-1}{2c} + \frac{c+1}{c}\right) u_0 \sin 2\theta + \frac{c+1}{2c} u_0 \sin 4\theta$$
 (24)

$$c = \frac{B_1 - A_1}{A_1} \tag{25}$$

$$u_0 = \frac{gP}{\pi} \frac{(B_1 - A_1)}{2A_1(\nu_1 - k - nk) - B_1(\nu_1 - k - nk)}$$
 (26)

$$A_1 = (19n + 11nk + 10k - 10v_1) + \mu(11n - 6nk + 15k - 15v_1)$$
(27)

$$B_1 = 10n(1-k) + 10\mu(3k - 3\nu_1 + 2nk + n)$$
 (28)

$$k = \sqrt{\frac{E_1}{E_2}} \tag{29}$$

$$n = \sqrt{2(k - v_1) + \frac{E_1}{G}} \tag{30}$$

$$g = \frac{1 - v_1 v_2}{E_2} + \frac{k}{G} \tag{31}$$

$$\Phi_{1} = A ln \zeta_{1} + \left(\frac{c-1}{2x} \frac{q_{2} - ip_{2}}{2D} - \frac{c+1}{c} \frac{ip_{2}}{2D}\right) \frac{u_{0}}{\zeta_{1}^{2}} + \frac{c+1}{2c} \frac{q_{2} - ip_{2}}{2D} \frac{u_{0}}{\zeta_{1}^{4}}$$
(32)

$$\begin{split} \Phi_2 = B ln \zeta_2 + \left(\frac{-(c-1)}{2x} \frac{q_1 - ip_1}{2D} - \frac{c+1}{c} \frac{ip_1}{2D} \right) \frac{u_0}{\zeta_2^2} \\ - \frac{c+1}{2c} \frac{q_1 - ip_1}{2D} \frac{u_0}{\zeta_2^4} \end{split} \tag{33}$$

Although the general solution by Lekhnitskii (1968) is for a hole in an infinite plate, the form of the stress functions proposed by Zhang and Ueng (1984) means that the vertical component of the resultant force applied to the plate is zero on the *y*-axis. These functions therefore approximate a semi-infinite plate with a half-hole, which is appropriate for the geometry in the experimental work described in Sect. 3.2.

It should be noted that this is only an approximate solution for a semi-infinite plate with a half-hole, because the shear stress on the *y*-axis is not zero. Zhang and Ueng (1984) show that this approximation does not affect the stress field significantly, and it is therefore assumed that it will not significantly affect the vertical deformations.

3.1.3 Superposition for displacements

The deformation of the dowel for a particular applied load, and particular support conditions, will, in general, be different from the deformation u_0 . The strain field is integrated to give the deformations in the plate, resulting, for this case, in one non-zero constant of integration, U in (6). In this paper, the constant is eliminated by superimposing the solutions for two holes loaded in opposite directions. By placing the second 2h below the first, as shown in Fig. 2, a line of zero displacement is created at a vertical distance h from the hole. If the holes are sufficiently well separated that there is no significant interaction between the stresses on the edges of each hole, then this is a reasonable representation of a plate supported rigidly along one edge.

In order to calculate the movement of the dowel, the displacement of the timber in the semi-infinite plate is calculated in two positions, u_0 at y=0, x=r and u_1 at y=0, x=2h-r. u_0 can be calculated directly using (26). For u_1 , the transformed coordinates ζ_1 and ζ_2 are calculated using (3) and (4). Since the point is on the x-axis, ζ_1 and ζ_2 are equal in both cases. Φ_1 and Φ_2 are then calculated using (32) and (33), for a unit applied force P. u_1 is then calculated using (6).

The displacement of the dowel relative to the fixed surface at x = h is then given by $(u_1 - u_0)/2$, and the predicted stiffness of the specimen can be calculated as $2/(u_1 - u_0)$.

3.2 Experimental method

The experimental testing consisted of three parts. First, the foundation modulus of the timber under dynamic loading was found. Then the parameters required for the analytical determination of the foundation modulus were investigated: the frictional resistance of the dowel in a half-hole and the elastic moduli of the timber in each grain orientation. The timber used was Douglas fir grown in the United Kingdom, which was stored for 12 weeks after delivery in a controlled environment, with the temperature maintained at 18–22 °C, and relative humidity at 60–65 %.

3.2.1 Foundation modulus

The experimental method is based on the static test method described in the ASTM standard (ASTM D 5764:1997). This method uses a piece of timber with a half-hole in its surface. In contrast, methods such as the European Norm (EN 383:2007) use a piece with a complete hole through the centre. Using a timber piece with a half-hole enables the dowel to be held rigidly straight, which means that the displacement of the dowel is uniform along its length, and the displacement of the loading head is an accurate measure of the deformation of the timber. This is particularly important given the high stiffness of the timber under dynamic loading, and the correspondingly small deformations that need to be measured in these dynamic tests.

A linear variable differential transformer (LVDT) was used to measure the displacement of the loading head, except when its 2 mm range was exceeded; in which case, the built-in displacement transducer in the servo-hydraulic loading machine was used. Figure 3 schematically shows the test setup and specimen dimensions for parallel- and perpendicular-to-grain specimens.

3.2.2 Static tests

In order to characterize the forces applied to the dynamic test specimens, their embedment strength was predicted according to Eurocode 5 (EN 1995), based on their density. The average density of 27 of the specimens was measured as 485 kg/m³, and the average moisture content of three preliminary specimens was obtained by the oven dry method according to the European Norm (EN 13183:2002), and found to be 14.9 %. On this basis, the adjusted density for the reference value of 12 % moisture content, used in Eurocode 5, was calculated as 453 kg/m³. After the dynamic tests had been carried out, eight of the dynamic test specimens were used for moisture content evaluation. The average moisture content was 14.6 %, with a coefficient of variation of 0.065. The preliminary moisture content measurement was, therefore, considered

sufficiently accurate for estimation of load capacity. The calculated embedment strength is shown in Table 1. Four static tests were also carried out, two in each grain orientation, to verify the calculated value. The average of those results is also shown in Table 1.

Since it would be the calculated value that would be used to design a connection in practice, the calculated embedment strength was used as the reference value for the forces applied in the dynamic tests.

3.2.3 Dynamic tests

Each specimen was subjected to 1,000 sinusoidal cycles of force at 1 Hz. The peak force was either 20, 40 or 80 % of the calculated embedment strength of the specimen.

The amplitude of the sinusoid was given by the R-ratio, as defined by (34), where F_{peak} is the maximum compressive force in the cycle, and F_{trough} is the minimum compressive force. Nominal R-ratios of 1.2 and 10 were tested.

$$R = \frac{F_{peak}}{F_{trough}} \tag{34}$$

Each combination of grain orientation, peak force and *R*-ratio was tested, resulting in a total of 12 tests. There were three repetitions of each, giving 36 specimens in total. The steady-state values of secant stiffness were assessed for comparison with the results of the analytical model.

The secant stiffness is taken as the slope on the force—displacement diagram between the points of maximum and minimum displacement in each 1 s period.

3.2.4 Friction tests

Tests were carried out to estimate the coefficient of friction to use in the analytical model. Figure 4 shows the test setup in which a vertical force was applied to two specimens, with a long dowel between. The vertical load was applied by a servo-hydraulic loading machine, which allowed the load to be held constant despite any vertical settlement. The dowel was pushed horizontally using a hydraulic hand jack, and the force required to do so was continuously recorded through a load cell.

It should be noted that the friction force in this test setup is in a different orientation to the friction force developed during embedment of the dowel into the timber. Tests by McKenzie and Karpovich (1968) showed that the grain orientation had no significant effect on the magnitude of

either the static or steady sliding friction coefficients. It is considered reasonable, therefore, to assume that the frictional behaviour will be similar in both orientations, so that this test provides a suitable estimate of the coefficient of friction for use in the analytical model.

Three tests were carried out with the load parallel to the grain, and three with the load perpendicular to the grain, using pairs of specimens with the same dimensions as those used for dynamic tests.

3.2.5 Elastic moduli

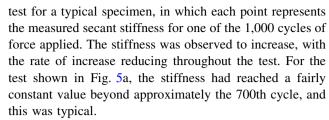

The principal elastic moduli were determined from tests on specimens extracted from some of the dynamic test specimens, following the method given in the European Norm (EN 408:2010). The specimens for which elastic modulus data were obtained are summarized in Table 2. Two elastic modulus specimens were taken from each dynamic test specimen, one in each grain direction, so 26 elastic moduli were obtained in each grain direction, 52 in total.

4 Results

4.1 Experimental results

4.1.1 Secant stiffness

The measured stiffness was not constant throughout each test. Figure 5a shows the variation of stiffness through the

Some parallel-to-grain specimens tested at R = 1.2, however, still exhibited a significant rise in stiffness at the end of the test, and the most extreme case is shown in Fig. 5b. The specimen therefore failed to reach a steady-state value of stiffness during the test. This had consequences for the comparison of these experimental results with analytical predictions, as discussed in Sect. 4.3.

The surface of the timber in contact with the steel will not have been perfectly smooth and tight fitting due to the drilling process and the heterogeneous microstructure of the timber. Part of this unevenness and lack of fit may have been gradually taken up under the applied force, so continually increasing the stiffness towards the value of the tight-fitting case.

The scatter in the calculated values of stiffness is thought to be due to a combination of two effects. One is that the finite sampling rate meant that the highest and lowest values of force and displacement in each cycle were not necessarily sampled. The other is that electrical noise in the force and displacement measurements would add a random component to each measurement, and, therefore, to the calculated stiffness. The scatter is, therefore, thought to be due to the measurement process and not indicative of the real behaviour of the specimen.

4.1.2 Effect of amplitude

Figure 6 shows the comparison of two force—displacement diagrams recorded for individual cycles of force on the same specimen. In this case, an oscillating force at R=10 was applied for 200 cycles after 1,000 cycles at R=1.2 had been completed, so each graph is for the same specimen. It can be seen that the secant stiffness is lower for the higher-amplitude cycle at R=10. This reduction in stiffness is caused by nonlinear behaviour under low forces. In fact, the force—displacement diagram for R=10 shows significant nonlinear behaviour and hysteresis, while the behaviour at R=1.2 is near linear.

It is thought that unevenness in the contact surface between timber and steel or lack of fit between the dowel and the hole may be taken up by the pressure on this surface, causing the behaviour to become more linear with higher forces. When the force is removed, in the R=10 case, the effect of unevenness and lack of fit may be seen again at the lower loads, causing a reduction in stiffness.

4.1.3 Collated results

In order to obtain a steady-state value of stiffness for comparison between the tests, the mean of the stiffness for each cycle after the 700th was used. These stiffnesses are plotted against the peak applied force in Fig. 7. The figures show that the peak applied force varied between repetitions of the same test, particularly in tests with a high peak load or a high amplitude of the load. This was because of the limited gain in the servo-hydraulic loading machine and the variability in specimen stiffness.

Where R=10 in both the parallel- and perpendicular-to-grain tests, it can be seen that the stiffness is generally lower than the corresponding tests with R=1.2. This is due to the effect of nonlinearity at low force, as described in Sect. 4.1.2.

There is a large scatter of stiffnesses in all the tests, but particularly in the perpendicular-to-grain tests. This was assumed to reflect the variation of material properties in the timber, and this assumption was tested by comparing these measured values of stiffness with predictions based on the material properties of the timber in the specimens and the coefficient of friction between the dowel and the timber, as described in Sect. 4.2.

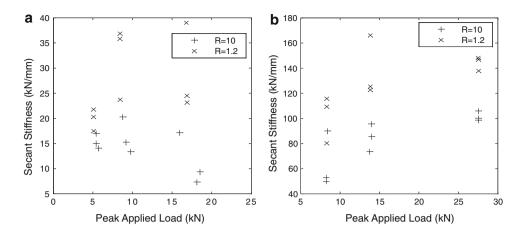

In each of the three tests parallel to the grain, with a peak force of 80 % of the embedment strength and R = 1.2, the displacement sensor was not correctly positioned for the first 1,000 cycles of force applied, so the results shown are for a second set of 1,000 cycles.

4.1.4 Friction tests

Six friction tests were carried out: three with the load applied parallel to the grain, and three with the load applied perpendicular to the grain. Figure 8 shows the plot of applied lateral force against lateral displacement for one of the friction tests. This highlights the influence of the rate of movement of the dowel. In part A of Fig. 8, the lever of the

hand jack was pushed down slowly, which meant that the applied force dropped away before the constant rate of displacement, required for kinetic friction, could develop. The dowel therefore moved a short distance each time and then stopped, a phenomenon known as stick—slip oscillation.

In part B of Fig. 8, the lever of the hand jack was moved sufficiently quickly that kinetic friction could develop, after overcoming the initial, higher force of static friction. Since there is continuous movement in the dynamic tests, it is considered that the coefficient of kinetic friction is appropriate as the input to the analytical model. The coefficient of friction to be used in the model was therefore estimated based on the kinetic friction in each case.

In some of the parallel-to-grain friction tests, since a higher vertical load was applied, it was not possible to depress the lever of the hydraulic jack quickly enough to achieve the kinetic friction behaviour as in part B. In these cases, the lower value of force in the stick-slip oscillation, as in part A, was used to estimate the coefficient of friction. Figure 8 shows that the lowest force measured in part A is a reasonable estimate of the coefficient of kinetic friction.

The mean ratio of the horizontal kinetic force to the vertical force for all six tests was 0.41, with a coefficient of variation of 0.1, giving an estimate of the coefficient of friction, for use in the model, of 0.21. There was no clear effect of grain orientation on the ratio of normal force to friction force.

4.1.5 Elastic modulus

The mean measured elastic modulus was 10,569 N/mm² in the parallel-to-grain direction, with a coefficient of variation of 0.21, and 322 N/mm² in the perpendicular-to-grain direction, with a coefficient of variation of 0.38.

4.1.6 Estimating shear modulus

The measured values of the principal elastic moduli provided two of the four parameters required for the analytical model. In addition, the Poisson's ratio and shear modulus are required. The Wood Handbook (Forest Products Laboratory 2010) provides mechanical properties for various species of timber, including Douglas fir. There are nine independent constants: three elastic moduli corresponding to the longitudinal, radial and tangential orientations with respect to the grain and ring structure; three shear moduli and three Poisson's ratios. The values for Douglas fir are summarized in Table 3.

The mean elastic moduli from these tests were 10,569 N/mm² in the longitudinal direction and 322 N/mm² in the perpendicular direction, which, for most specimens, was close to tangential. The ratio of the two moduli, was, therefore, quite different from that given in the Wood Handbook (Forest Products Laboratory 2010). It was not, therefore, considered appropriate to obtain the

Table 3 Mechanical properties for Douglas fir, taken from the Wood Handbook (Forest Products Laboratory 2010)

E _L (N/mm ²)	E _T (N/mm ²)	E _R (N/mm ²)	G _{LR} (N/mm ²)	G _{LT} (N/m ²)	G _{RT} (N/mm ²)	v_{LR}	$\nu_{ m LT}$	v_{RT}
14740	737	1002	943	1150	103	0.292	0.449	0.390

shear modulus as a proportion of the longitudinal elastic modulus, using a ratio from published results. Another rationale was therefore sought to estimate the shear modulus.

Jones (1975) shows that if the elastic compliances of an orthotropic material in plane strain are given by s_{ij} , as in (35), then the apparent shear compliance, s'_{66} , for axes at an angle θ to the principle axes, is given by (36).

$$s_{11} = \frac{1}{E_1}$$
 $s_{12} = \frac{-v_{12}}{E_1}$ $s_{22} = \frac{1}{G_{12}}$ (35)

$$s'_{66} = 4(s_{11} + s_{22} - 2s_{12})\sin 2\theta \cos 2\theta + s_{66}(\sin 2\theta - \cos 2\theta)^{2}$$
(36)

For Douglas fir, as described in the Wood Handbook (Forest Products Laboratory 2010), the variation of apparent shear modulus with angle in the longitudinal-tangential plane can be plotted using (36). The result is shown in Fig. 9.

At $\theta=45^\circ$, s'_{66} is independent of s_{66} , and so the apparent shear modulus is independent of the principal shear modulus. Using the elastic moduli obtained from the tests, it was therefore possible to calculate the apparent shear modulus at $\theta=45^\circ$ for each specimen. The ratio of

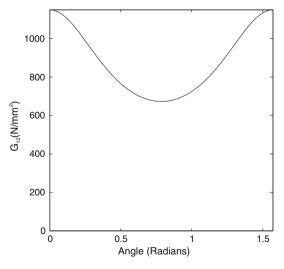

Fig. 9 Variation of apparent shear modulus with angle from the principal direction for Douglas fir

Abb. 9 Statischer Schubmodul von Douglasie in Abhängigkeit des Winkels zwischen Kraft- und Faserrichtung the maximum and minimum shear modulus from Fig. 9 was then assumed to apply to the Douglas fir used in the tests, and was used to estimate the principal shear modulus for each specimen.

4.2 Analytical results

4.2.1 Analytical models

The two elastic moduli obtained from the tests, the Poisson's ratio for the longitudinal-tangential plane taken from the literature and the shear modulus estimated as described in the previous section were used to create a set of analytical models for the dynamic test specimens. Using these material properties and applying a unit force, the value of the two stress functions could be calculated at each point in the specimen. Using the stress functions, the displacement of every point in the specimen can be calculated. Those displacements are plotted, for illustrative purposes, in Fig. 10.

No free edge effects are allowed for on the sides of the specimen. The edge distances are considered to be

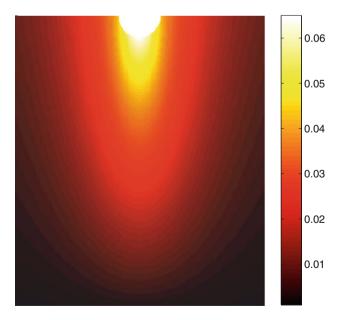

Fig. 10 Vertical displacements in mm in the timber for a typical specimen in parallel-to-grain loading (1 kN applied force) **Abb. 10** Vertikale Verformung im Holz in mm für einen typischen in Faserrichtung belasteten Prüfkörper (1 kN aufgebrachte Last)

sufficient that the other free edges will not significantly influence the stress or deformation fields.

4.2.2 Sensitivity to friction coefficient

The sensitivity of the analytical model to the friction coefficient was assessed by varying the coefficient between the extremes of values published by McKenzie and Karpovich (1968), from their study of friction between steel and timber. For comparison with their work, the rate of movement between the surfaces in these tests corresponds to their classification 'slow', and the surface of the steel dowel falls between his classifications of 'rough' and 'smooth'. For all the species of timber tested, the friction coefficient in these classifications ranged from 0.08 to 0.62. Using the material properties for one of the parallel-tograin dynamic test specimens, the sensitivity analysis is summarized in Table 4, comparing these extreme values to the mean value obtained from the friction tests and used in analysis, 0.21. The resulting variation in stiffness is small in comparison to the variability in material properties in the timber. It is, therefore, considered that the sensitivity of

4.2.3 Comparison with experimental results

The mean and range of analytical results was compared with the mean and range of experimental results for each grain orientation, and for each *R*-value. The predicted values of stiffness are independent of the magnitude of the force applied due to the assumption of elastic behaviour. The results for the three values of peak force were, therefore, combined for this comparison of predicted and measured stiffness. Figure 11 plots the range of stiffness and the mean stiffness for the experimental results and the analytical model, with the results organized by grain orientation and *R*-value.

4.3 Discussion

Where the amplitude of vibration is smallest, in the tests with R=1.2, the range of predicted values and measured values are similar, as are the mean values for each set. This suggests that the elastic model is appropriate for prediction of the foundation modulus for small-amplitude vibration. For the perpendicular-to-grain tests, the mean predicted stiffness is within 5 % of the mean measured stiffness. For the parallel-to-grain tests with R=1.2, the measured values are lower than predicted. The mean measured stiffness is approximately 14 % lower than the mean predicted value in these tests. As noted in Sect. 4.1.1, for some of these tests, a steady-state value of stiffness was not achieved.

The measured stiffness in each cycle continued to rise until the end of the test. It is, therefore, possible that, if the tests were continued, values of steady-state stiffness closer to the predicted values might be reached.

For the greatest amplitude of load, where R = 10, the predicted stiffness is significantly higher than the measured stiffness in the dynamic tests both parallel- and perpendicular-to-grain. This can be explained by the reduced secant stiffness in these tests due to nonlinear behaviour at low force, as described in Sect. 4.1.2.

5 Conclusion

Comparison of the analytical model and the experimental results shows that, for small-amplitude vibrations and once a steady-state dynamic response has developed, an elastic orthotropic model is appropriate to estimate the dynamic stiffness of the specimen. There is considerable scatter in the measured stiffnesses between the tests, but this is reflected in the measured variation in elastic moduli. The measured stiffness is lower than predicted in the parallel-to-grain tests, and this is thought to be a result of the imperfection of the contact surface between steel and timber not being fully compressed under the applied loads.

The model presents a method to relate the fundamental material properties of the timber to its behaviour as part of a connection, and this is done through a compact analytical equation. The simplicity of the calculation means that it may be applied in circumstances in which a more detailed numerical model is inappropriate, due the time or computational expense that would incur.

When the amplitude of the oscillating force was increased, even though the peak force was not increased, the specimens behaved in a more nonlinear way. This nonlinearity reduced the secant stiffness which was measured below the predicted elastic stiffness. It would seem appropriate to apply some factor in design to allow for the fact that, while an elastic analysis is appropriate for small-amplitude vibration, a reduced stiffness is expected as the amplitude of vibration increases. Definition of such a factor would require further tests with a range of amplitudes of force.

The analysis has been applied to a particular geometry in this case, in order to match a standard test method for determining the foundation modulus for a dowel-type connection in timber. In reality, the foundation modulus will depend on the geometry of the timber around the connector. Further work will seek to apply the analysis method to geometries which occur in real structures.

Acknowledgments Thanks to Will Bazeley and Neil Price for their help and guidance in carrying out the experimental work.
